Abstract

A fundamental part of many authentication protocols which authenticate a party to a human involves the human recognizing or otherwise processing a message received from the party. Examples include typical implementations of Verified by Visa in which a message, previously stored by the human at a bank, is sent by the bank to the human to authenticate the bank to the human; or the expectation that humans will recognize or verify an extended validation certificate in a HTTPS context. This paper presents general definitions and building blocks for the modelling and analysis of human recognition in authentication protocols, allowing the creation of proofs for protocols which include humans. We cover both generalized trawling and human-specific targeted attacks. As examples of the range of uses of our construction, we use the model presented in this paper to prove the security of a mutual authentication login protocol and a human-assisted device pairing protocol.

Keywords: Ceremony; human; HTTPS; TLS; provable security; authentication; HPA; protocol.

1 Introduction

Practice-oriented provable security, for authentication protocols, was introduced by Bellare and Rogaway in 1993 [1]. Since this time, many authentication protocols have been proven secure in theory, only to fail to meet this level of security when used in practice by a human. Increasingly there has been a realisation that to create secure protocols which involve humans, human capabilities need to be an explicit consideration of the security model, as exemplified by Shostack and Stewart’s statements, “…our approach to information security is flawed” and “the way forward cannot be found solely in mathematics or technology” [11].

We focus on authentication protocols involving a human, in which the human is expected to authenticate the party they are communicating with. This may be either mutual authentication or one-way authentication. For such protocols, the human is expected to recognize an authenticator, or perform some task which accepts some security information as input and outputs either accept or reject. In this way we build on the recognise function introduced by Gajek et al. [5,6] in their work on authentication to a human in a protocol using TLS. We focus specifically on the recognise functionality a human must perform, and create a formalisation which may be reused in all such protocols.

A formal construction of the human’s recognise capabilities can be used in a variety of types of protocols. As already mentioned, there are uses such as the Gajek et al. protocol, which is similar to protocols that have been implemented by numerous financial institutions. Similarly, the construction allows for formal analysis of implementations of the widely used Verified by Visa protocol. In this protocol a message that the human entered on first use of the system is sent back to the human to authenticate Visa to the human in all future executions of the protocol.

Less obvious real world protocols, which our construction may also permit formal analysis of, are authentication protocols over a telephone between two humans. A common example is where an investor calls her stockbroker using the telephone, says a password to the stockbroker, and the stockbroker ensures that the password said by the investor matches the password stored for that investor. Even login messages meant to allow users to compare the last time the system recorded their login credentials were used, or technology” [11].
time within five attempts. As the attack became more targeted, success rates increased, with non-trusted and semi-trusted acquaintances being able to guess correctly 17% of the time, and trusted acquaintances being able to guess correctly 28% of the time [10]. This means that the severity and likelihood of success of an attack varies greatly, depending on whether the attack is a targeted attack or a trawling attack.

We will show a range of uses for our formalization, with two examples of adaptations of security proofs. We will show how our approach may be applied in the case of a web-based mutual authentication protocol (see Section 3), and in the case of human-assisted pairing of two Bluetooth devices (see Section 4.1). The former will cover the case of human-selected authenticators, while the latter will provide an example of device-selected authenticators. In both cases the central human recognise step remains critical and constant.

### 2 Security Model for Human-Based Recognition

The security model describes the human’s role in recognising information sent to the human, which is a typical process in a protocol where the human authenticates a second party. The model formally describes how an attacker interacts with the human, and what capabilities and constraints the attacker has.

#### 2.1 Formalisation

We begin by describing the situation where a human generates a HPA which they memorize. A HPA is a human perceptible authenticator. Subsequently, some information, HPA′, is generated by another party and is sent to the human. The human assesses the HPA′ by comparing the received HPA′ to the HPA they have stored in memory. A concrete illustrative example may be the case where the human selected HPA and the HPA′ generated by the other party are images and the human checks to see if the two images HPA and HPA′ are equal.

A central ideal we have incorporated is that this behaviour will be different from human to human. That is, HPAs that a human generates will be human specific. We shall call HPAs that are specific to a human HPAH. While in one context an example use of the HPA is that the human shares the HPA with an entity, so that the entity can use the HPA to authenticate to the human, this may not be the case all of the time as HPA’s could be generated by the entity and given to a human in a setup stage. Therefore we focus exclusively on the recognise step common to most device-to-human authentication protocols. That is, a HPA is received by the human, the human compares the HPA′ with their HPA, and either accepts or rejects that HPA′ is the same as HPA.

##### 2.1.1 HPA Scheme

We defined HPASpace to be the space of HPAs. To use the traditional example of alphanumeric passwords, for a specific protocol this space may be bounded by the 94 character possibilities, consisting of 26 lowercase, 26 upper case, 10 numerals and 32 special printable characters, and the number of characters accepted for the password. For example, for eight characters, this is 94^8 possibilities.

The value of HPAH is the output of a probabilistic algorithm GenHPA which is specific to each human, and hence accepts as inputs the human H and the HPASpace of the protocol being analysed, $\text{HPA}_H \leftarrow \text{GenHPA}(H, \text{HPASpace})$.

To return to the example of an alphanumeric password, it is widely known that while the likelihood of selecting a randomly selected eight character password may be 94^8, or approximately 53 bits of security, non-random human selection typically brings this figure closer to 30 bits of security for humans in general [3]. However, for a specific protocol, the set of alphanumeric passwords generated may be far smaller [5], and hence the output $\text{HPA}_H$ will be part of the human’s specific HPASpace i.e.

$$\text{HPASpace}_H = \{\text{HPA}_H | \text{HPA}_H \leftarrow \text{GenHPA}(H, \text{HPASpace})\}.$$  

Notice that $\text{HPA}_H \in \text{HPASpace}_H \subseteq \text{HPASpace}$.

The function Recognise is defined to model the human’s ability to take two inputs, HPA and HPA′, one potentially in memory and the other being presented to the human, and compare the two inputs. If, in the human’s opinion, there is a match between HPA and HPA′ then Recognise outputs a one, otherwise Recognise outputs a zero. This models the human’s assessment of “The two values are the same.” Therefore, the Recognise algorithm depends on the human:

$$0/1 \leftarrow \text{Recognise}(H, \text{HPA}, \text{HPA}')$$

Of course, no human performs the recognise function perfectly 100% of the time. There will be both false positives and false negatives from the Recognise function. False positives occur when the human assesses there is a match between HPA and HPA′ and yet the two values are different. False positives are seen as being a result of human’s inability to distinguish between two objects, if they are similar enough though not identical, and are discussed in detail below. False negatives result when HPA = HPA′ and yet the human assesses there is no match, and the recognise function outputs a 0. False negatives, for example the human being presented with two identical pictures and yet assessing them as different, are seen as an error condition, modelled by an error probability $\epsilon$. False negatives are in agreement with Hopper and Blum’s $(\alpha, \beta, t)$ method of describing human protocols, where value $\beta$ is the probability of the human not successfully executing the protocol [7].

##### 2.1.2 Human Indistinguishability

We denote the set of different HPA’s which the user recognises as being indistinguishable from their chosen HPA as being the set $\text{W}_{\text{H},\text{HPA}}$. This is the set of the actual HPA and false positives. Note that a HPA′ that is recognised by a human as being indistinguishable from their HPA may come from their human specific HPASpace or from the general HPASpace. For the sake of analysis of a specific protocol, we explicitly exclude any other object in existence which is not from HPASpace. That is, if the HPASpace of a system is defined as a four digit personal identification number, then a five digit personal identification number would not be a valid HPA. This commonly accepted constraint is a limitation of our approach, since there may be objects from outside HPASpace which the human will accept as being their HPA.
To aid in the understanding of how the set of false positives \( W_{H,HPA} \) interacts with \( HPASpace \) and \( HPASpace_H \), the relationship is depicted in Figure 1. These false positives form a set of HPAs, specific to a human, which are similar enough (or human indistinguishable) that the Recognise function will output a 1 for a given HPA:

\[
W_{H,HPA} = W'_{H,HPA} \cup W''_{H,HPA}
\]

where \( W_{H,HPA} \) is the set of HPAs from \( HPASpace_H \) and \( W'_{H,HPA} \) is the set of HPAs from \( HPASpace \) which are not in \( HPASpace_H \). Formally:

\[
W'_{H,HPA} = \{ HPA' \in HPASpace_H | Recognise(H, HPA_H, HPA') = 1 \}
\]

and

\[
W''_{H,HPA} = \{ HPA' \in \{ HPASpace \setminus HPASpace_H \} | Recognise(H, HPA_H, HPA') = 1 \}
\]

with \( HPA_H \leftarrow GenHPA(H, HPASpace) \).

The relationship between \( W'_{H,HPA} \) and \( W''_{H,HPA} \) and \( HPASpace \) is shown in Figure 2.

### 2.1.3 Security and Usability

An interesting distinction between false positives and false negatives is made when considering security and usability. False positives result in a less secure system. False negatives do not impact security. If a human is presented with \( HPA' \) which equals \( HPA \) but does not assess that this is a match, then the protocol will be aborted and hence the system will remain secure. However, false negatives do impact usability in that if the protocol does not successfully proceed when \( HPA' = HPA \), then the human will not be able to use the system, or at the very least the human will need to execute the protocol one time more than they needed to. This is similar to the well known trade-off in biometrics.

### 2.1.4 Probabilistic versus Deterministic

In our formalism, \( W_{H,HPA} \) represents the set of HPAs which the user recognises (mistakenly, except in the case where \( HPA' = HPA \)) as being indistinguishable from their chosen HPA. We have captured that this may vary from human to human. We also, in Definition 2, capture that sometimes the real HPA will not be recognised as being the real HPA by the human. Finally, we capture that the set of HPAs that a specific human may pick will be different from human to human, in our definition of \( GenHPA \).

However, while this variability is captured and gives useful results, the set \( W_{H,HPA} \) is constant and deterministic for a human in our model, whereas in reality such a set may vary over time particularly with context. Further, the set \( HPASpace_H \) is constant in our model, and again this set may vary with context.

### 2.2 Security Definition for Human Recognition

In our model, we define security in terms of the adversary \( A \)'s ability to obtain a HPA value which will cause the human to output a 1 from the Recognise function.

The security game proceeds as follows. A HPA is generated for a specific human \( H \) using the \( GenHPA \) algorithm. This models a human selecting their HPA.

\[
HPA_H \leftarrow GenHPA(H, HPASpace)
\]

The adversary \( A \) knows \( HPASpace \) and gets oracle access to \( Recognise(H, HPA_H, \cdot) \) and \( GenHPA(\cdot, HPASpace) \).

\[
HPA' \leftarrow A(Recognise(H, HPA_H, \cdot), GenHPA(\cdot, HPASpace))
\]

Access to the \( GenHPA \) oracle models \( A \)'s ability to gain information about expected HPAs from humans, including the target human. That is, we have not limited \( A \) to using the \( GenHPA \) oracle on only the target human. This allows \( A \) to use the \( GenHPA \) oracle to effectively construct \( HPASpace_H \), including frequency distribution, for both the target \( H \) and other humans. We call this constructed \( HPASpace_H \), “\( HPASpace'_H \)”. This is now a targeted attack, which is more damaging than a general attack. Access to the Recognise oracle allows \( A \) to test \( A \)'s selected \( HPA' \) to see if the selected \( HPA' \) is accepted.
2.2.1 Upper Bound on A’s Probability of Success

The adversary can either work from $H_{PAS}$ or generate a $H_{PAS}^r$ for the human using the $Gen_{HPA}$ oracle. As shown in (1), $H_{PAS}^r$ contains at most $q_{gen}$ elements, where $q_{gen}$ corresponds to the number of $Gen_{HPA}(H, H_{PAS})$ queries.

If the adversary selects from $H_{PAS}^r$ then the attack is described as a general attack, whereas if the adversary selects from $H_{PAS}$ then the attack is described as a targeted attack.

**Targeted Attack** $A$ selects an authenticator $HPA$ from $H_{PAS}^r$, creating a targeted attack. In this case,

$$\text{Succ}_{A_{human}} = \Pr[A \text{ wins}] \leq \max_{H_{PAS}} \frac{q'[W_{H, H_{PAS}^r}]}{|H_{PAS}|} \cdot \Pr[HPA^*] \quad (2)$$

where $q'$ is the number of queries to the Recognise oracle to test a $HPA^*$ generated using queries to the $Gen_{HPA}$ oracle, and $\Pr[HPA^*]$ is the probability of $HPA^*$ being generated by $Gen_{HPA}$. This is the case of the targeted attack against a human, by $A$ somehow having knowledge of $HPA$ choices for that human (perhaps by knowing $HPA$s used by that human on other systems).

Prior work by Gajek et al. [5] considered only non-human-specific indistinguishability, and from the entire $H_{PAS}$ ($|W_{H, H_{PAS}}|$). In addition to adapting this to the human-specific targeted attack setting, the upper bound on $A$’s probability of success must take into account the likelihood that a $HPA$ is generated by $Gen_{HPA}(H, H_{PAS})$.

Intuitively, a $HPA^*$ with a large $|W_{H, H_{PAS}^r}|$ is unlikely to be the upper bound on $A$’s success probability if the likelihood that $HPA^*$ is picked as the authenticator is minute. This introduces the concept of the frequency of use of $HPA^*$. Therefore, for the targeted attack, informally the maximum of the frequency of use $\Pr[HPA^*]$ combined with the size of set $W_{H, H_{PAS}^r}$ is the upper bound on $A$’s success.

**Trawling Attack** $A$ picks an authenticator from the general $H_{PAS}$. In this case,

$$\text{Succ}_{A_{human}} = \Pr[A \text{ wins}] \leq \max_{HPA^* \leftarrow H_{PAS}} \frac{q''[W_{H, H_{PAS}^r}]}{|H_{PAS}|} \quad (3)$$

where $q''$ is the number of queries to the Recognise oracle with corresponding no prior query to the $Gen_{HPA}$ oracle. This is the case of the general trawling attack, with no prior knowledge regarding the human’s choices, such that the adversary has to select from the entire $H_{PAS}$.

Usually we can expect that the targeted attack is more likely to be successful than the trawling attack, but there could be exceptional cases in which this is not true. Therefore, in general the probability from Equation (2) may be a more exact upper bound on the adversary’s success probability. However without access to $Gen_{HPA}$ the upper bound remains as in Equation (3). We can now define what it means for our schemes to be secure and correct.

**Definition 1** ($\delta$-security). We say a $HPA$ scheme is $\delta$-secure, meaning that the scheme can be used as an authentication scheme for an entity to a human, if

$$\text{Succ}_{A} \leq \delta.$$

**Definition 2** ($\epsilon$-correctness). We say a $HPA$ scheme is $\epsilon$-correct if, for all $HPA^r$, in $H_{PAS}$, where $HPA^r \leftarrow Gen_{HPA}(H, H_{PAS})$,

$$\Pr[\text{Recognise}(H, H_{PAS}^r, H_{PAS}) = 1] \geq 1 - \epsilon$$

where $\epsilon$ represents the false negative rate of correctness. For correctness, we are not concerned about false positives, which is covered by $W_{H, H_{PAS}}$.

2.3 Analysis and Discussion

The $H_{PAS}$ will be system specific. Using a classic human authenticating scenario which may be adapted to create mutual authentication, a system for banking Personal Identification Numbers (PINs) may have a $H_{PAS}$ limited to four numerical digits, while other systems may have graphical or alphanumeric $H_{PAS}$. The effect of $Gen_{HPA}$ taking as an input $H_{PAS}$ is that comparison between security results for different systems can be made.

Giving the adversary $A$ oracle access to the human specific $Gen_{HPA}$, allows the modelling of the effect of $HPA$ reuse and of the preferences of the user. If the size of $H_{PAS}$, the output of $Gen_{HPA}$, is less than the size of $H_{PAS}$, then the adversary receives an advantage. There may be instances where $A$ does not get this capability, depending on whether the attack is targeted or trawling attack. A targeted attack is by far the stronger and more damaging attack, as in the real world would model the case where an adversary has knowledge of a human’s $HPA$ choices. This knowledge may exist because the adversary may be a legitimate server where the human logs in elsewhere, and thus the adversary has seen many prior examples of the human’s $HPA$ choices.

In general, ensuring that $Gen_{HPA}$ and $\text{Recognise}$ are human specific functions, allows for modelling of targeted attacks at a specific human. Giving $A$ oracle access $\text{Recognise}(H, H_{PAS}^r, \cdot)$ to the human specific $\text{Recognise}$ function means that an adversary with infinite resources could create the set $W_{H, H_{PAS}}$ for a given $HPA$.

3 Human-Specific $HPA_{Gen}$

In this section we will describe the case where a human chooses the $HPA$. In the next section, we will cover the alternative case where a device selects the $HPA$ for the human.

Our formalisation, as defined allowing for targeted attacks, is ideal for use in existing device-to-human (D2H) authentication scenarios, such as the protocol by Gajek et al. [5], or protocols involving authentication by humans in general.

3.1 Gajek et al. Browser Based Mutual Authentication over TLS

Gajek et al. have created a mutual authentication protocol including a human and a $HPA$. A sketch of the Gajek et al. protocol, including a description of where the $HPA$ is used and how the human $\text{recognise}$ function is applied, follows [5, 6]:

1. The protocol is between a server, a human’s computer running a web browser (which has state), and the human.
2. Before the protocol begins, the human has selected a HPA and provided that HPA to the server. The HPAs suggested by Gajek et al. are a personally selected image or voice recording.

3. Both the server and the human’s computer have authentication certificates and associated private keys, and a secure TLS connection is established between the browser and the server, when the browser on the human’s computer opens the server’s webpage. This process authenticates the server to the human’s browser and the human’s browser to the server.

4. The server sends the human the HPA that the human has stored with the server (by completing a lookup of the human’s browser-specific certificate, to know whose HPA to send), via the web browser which renders the HPA for the user. This step authenticates the server to the human if the human recognises the HPA.

5. Having recognised the HPA, the human sends the server their traditional login and password. This step authenticates the human to the server.

Our formalisation makes proof of such a protocol more complete by replacing game 20 of their proof [6]. The sketch of their proof is that SSL is proven in a certificate or SSH-based key exchange protocol. Our proof goes beyond the Gajek et al. proof, the result of the computer and securely present a form module (TPM) could be used to securely assess just the human and a device, such as a trusted platform module (TPM) to generate HPAs uniformly over HPASpace. A typical W_{H, HPA} may consist of any picture with a similar number of white (or black) pixels as HPA. Since the HPAs are device controlled, A’s advantage would be limited by Equation (3). Modelling the login procedure in this way would allow adjustment of security parameters such as the number of pixels and the number of colours in the image constructed by the TPM and presented to the user when they login, to arrive at the desired security for the login procedure.

3.2 Human-based Recognition with Non-human Controlled Authenticators

This leads us to the many practical protocols in use where HPAs have been chosen by devices or the system, rather than by the human. From a usability perspective, a human may be able to better remember a HPA they have selected. However, the essence of a D2H authentication protocol, where a human recognises some information (HPA) sent by the device, is that the HPA has been previously agreed on by the human and the device. Whether a human registers a HPA at a bank, or whether the bank sends the human a HPA in a setup stage, is irrelevant from the perspective of whether the protocol will function. In either case, the HPA can be sent to the human by the bank in all future protocol runs to authenticate the bank to the human.

Having the HPA chosen by the device means that HPASpace_H, the subset of HPASpace which the HPA will be in, encompasses all of HPASpace. This is because the device will choose the HPA from the entire HPASpace by a probability distribution, presumably a random distribution. From a security perspective, this maximises the space that the adversary has to select from to acquire a HPA which the user will recognise as their HPA. Having the HPA chosen by something other than the human, shifts the upper bound available to the adversary from a more powerful targeted attack to a weaker traveling attack.

We now adapt our formalisation towards non-human specific HPA selection, where non-targeted general traveling attacks apply. We focus on more general cases, such as human-assisted pairing protocols.

4 Non-Human-Specific HPAGen

Humans are often called on to play a part in protocols for the authentication of devices. For example, an authenticated key agreement (AKA) protocol employing short authenticated strings (SAS) may be used to manually pair wireless devices by having the user check matching values on each device [8].

by the trusted module for the human. That is, the TPM creates a list of hashes from different stages of a computer’s boot sequence, and these hashes are graphically presented to the user in some way. Thus, the computer’s TPM could be used to securely assess the computer and securely present a HPA to the user where the HPA’s construction (rendering by the TPM) depends on the status of the computer. As long as nothing has changed on the computer, then the same HPA will always be shown to the user to recognise each time she logs in, otherwise a completely new HPA will be sent to the user (i.e. in the same way that a one bit change will create a completely new HASH value). So a possible concrete implementation may be a 64 pixel black and white picture, 8 pixels high by 8 pixels wide, so the size of HPASpace would be 2^{64}. GenHPA would be generated by the trusted platform module to generate HPAs uniformly over HPASpace. A typical W_{H, HPA} may consist of any picture with a similar number of white (or black) pixels as HPA.

where Succ_A_{Human} is defined by either Equation (2) or Equation (3). This is in contrast to the corresponding equation in the original proof [6], using our notation:

$$\left| \Pr[Win_{20}] - \Pr[Win_{19}] \right| \leq \text{Succ}_{A_{Human}}$$

where W is the number of executions of the protocol.

The above demonstrates how our formalism can be used in a certificate or SSH-based key exchange protocol. Our proof goes beyond the Gajek et al. proof in the following areas:

1. In the Gajek et al. proof, $A$ selects from all of HPASpace, roughly equivalent to our travelling attack, whereas our proof allows for a targeted attack where $A$ selects from the human-specific HPASpace_H.

2. Our model covers the concept of frequency of use of a HPA, not just the size of $|W|$.

Furthermore, the technique used here can be applied to any authentication protocol, password authenticated key exchange (PAKE) protocol or key agreement protocol which requires the human to authenticate a message in the protocol. While these examples are network based, there are examples of use involving just the human and a device, such as a trusted computing scenario where a computer’s trusted platform module (TPM) could be used to securely assess the computer and securely present a HPA to the user.

An example trusted computer scenario may involve a login procedure where a picture is constructed
In such device pairing protocols, two HPAs are sent to a human, and if the human recognises the two HPAs as matching and accepts, then the human takes an action and the devices become paired. As always, the HPAs can be any human perceptible authenticator, such as two series of sounds, two series of flashing lights, or text or images displayed on a screen. We formalise this process by setting the HPA variable to the output of a probabilistic algorithm GenHPA which selects from the HPASpace of the protocol being analysed, i.e.

\[ HPA \leftarrow \text{GenHPA}(\text{HPASpace}) \]

Note the removal of the human from the GenHPA step, and hence the space of the generated HPA is HPASpace not HPASpace_H as it has been in the human generated HPA case. The Recognise function remains human specific, and the adversary’s win condition remains:

\[ \text{Recognise}(H, HPA, HPA') = 1 \]

Since HPASpace_H is now the size of HPASpace and hence the upper bound is as for a general trawling attack, the bound on A’s probability of success for a device chosen HPA is

\[ \text{Succ}_A = \Pr[A \text{ wins}] \leq \max_{HPA' \leftarrow \text{GenHPA}(\text{HPASpace})} \left[ \frac{|W_{1, HPA'}|}{|\text{HPASpace}|} \cdot \Pr[HPA'] \right]. \]

4.1 Human-based Recognition with Two Devices

An example implementation, which could now be rigorously examined using our formalisation, is pairing protocols for Bluetooth devices. When using human assisted pairing of devices using Bluetooth, one method is for protocols based on short authenticated strings (SAS). In these protocols, the SAS are somehow represented on two devices for a human to compare, using for example audible tones or flashing lights. Now these protocols involving a human can be examined formally using our model.

We will demonstrate how to incorporate our formalism by providing a security proof of Prasad and Saxena’s human-assisted Bluetooth pairing protocol [9] which is based on Pasini and Vaudenay’s SAS protocol shown in Figure 3 [8]. Pasini and Vaudenay’s protocol is designed to allow for the authentication of a potentially large message, by comparing two short strings. Note that by ensuring the messages came from a specific party, i.e. authentication, this also ensures integrity has been maintained. That is, if a third party changes the message, thus breaking integrity, then the message no longer originates from the initial party that sent the message. So the intention of the Pasini and Vaudenay protocol is to have no confidentiality of the messages sent, but have assurances of integrity and know who has sent the messages.

In Pasini and Vaudenay’s protocol, there is a critical final step over an authenticating channel. Using Vaudenay’s definition of this channel from [13] “The authentication channels provide to the recipient of a message the insurance on whom sent it as is. In particular, the adversary cannot modify it (i.e. integrity is implicitly protected), . . . (the) channels are not assumed to provide confidentiality.” The SAS protocol in Figure 3 employs a commitment scheme (commit, open) and a keyed hash function. An overview of the protocol is:

1. Alice selects a string \( K \) of length \( \kappa \) at random.
2. Alice commits to the value \( K \) and their message \( m_A \). This commitment is \( c \). The commitment is such that Alice cannot later manipulate the value of \( K \) having seen what value Bob later sends.
3. Alice sends \( c \) and \( m_A \) to Bob.
4. Bob then picks \( R \) at random and sends \( R \) and their message \( m_B \) to Alice.
5. Alice sends \( d \), used to open the commitment scheme, to Bob.
6. Bob uses \( m_A \), \( c \) and \( d \) to create (or “open via the commitment scheme”) \( K \). The hats on the values (shown in Figure 3), that is, comparing \( c \) with \( \hat{c} \), indicates that the value has passed over an insecure channel. Thus the value at Bob, \( \hat{c} \), may no longer be the original \( c \) created by Alice.
7. Finally, both parties create a string, SAS, using a keyed hash function. Both parties XOR (\( \oplus \)) \( \hat{R} \) with the output of a hash, keyed with \( K \), of the value \( m_B \).

Informally, to give an intuitive understanding of the benefits of the protocol, note that by both parties XORing \( R \) with the output of a hash of the value \( m_B \), with the hash keyed with \( K \), and by comparing the SAS values the two parties create, if the SAS values are equal then the following values must have been the same:

\[ K \]

Otherwise the hashes would output different values.

\( R \)

Otherwise the result of the XOR would be different. Note the use of the commitment scheme which generates \( K \) and the order of the protocol ensures \( R \) is sent and known before the output of the hash can be computed.

\( m_B \)

Otherwise the hashes would output different values.

\( m_A \)

Otherwise the opening of the commitment at Bob would have resulted in a different \( K \) at Bob, which would have meant the keyed hashes would have output different values.

Thus, if the two SAS values are the same, then the messages \( m_A \) and \( m_B \) have been successfully sent between the parties without being changed by a third party.

Prasad and Saxena’s adapted protocol exchanges and authenticates public keys by instantiating \( m_B \) from Figure 3 as \( \text{pubA} \), and, critically, the human makes the authentication assessment, thereby taking the role of Pasini and Vaudenay’s authenticating channel. Thus, by comparing two short strings, the (far longer) public keys are authenticated. Note that the protocol of Pasini and Vaudenay’s is well suited for exchanging public keys, as the keys are public but there must be assurances that the keys belong to the original senders, as is the goal of the Pasini and Vaudenay protocol.

The authentication assessment is made possible by transforming the constructed SAS string into a series of audible tones (beeps) or flashing lights (blinks) for the human to compare and, if the assessment is that the devices are the same, to accept and pair the devices. We shall call this protocol the Beep-Blink protocol. The adapted authentication stage of the protocol [9] is shown in Figure 4.
output a distribution of which may be very well known, which GenHPA cols, or the transformed SAS into beeps and blinks, HPA Space used. Firstly that the humans did not act perfectly, and secondly. Indeed, their human study [9] clearly showed to go beyond the presumption of humans acting perfectly. We have shown that it is necessary the protocol and how these can be dealt with in the what extent human errors may impact the security of does not commit any errors.” This leaves open to ing SAS protocol under the assumption that the user scheme is equivalent to the security of the underly- ena are also, though different, HPA s from different HPASpaces. An interesting philosophical point is that even 1s and 0s for voltage levels in a circuit have already undertaken a transform to be human recognisable. So and 0s for voltage levels in a circuit have already un- and being sent a HPA ′ as the two HPA inputs to the Recognise function, HPA A will be on device A, and HPA B will be on device B. The formalisation for the human specific version of Recognise, including the concept of W H,HPA as the set of HPAs which are indistinguishable for that human, still apply. While the intention of the Prasad and Saxena protocol would seem to be that the human either accepts on both devices or rejects on both devices [9], there clearly exists the case where on one device the human selects “Accept” and on the other device the human selects “Reject”. As such, for device A, their (potentially transformed) SAS is held as HPA and the SAS supplied by device B will be HPA ′; and similarly for device B. The authentication stage of Prasad and Saxena’s protocol, using our formalism, is shown in Figure 5. We now use our contribution to present a proof of the Prasad and Saxena protocol, capturing some useful human considerations.

Prasad and Saxena [9] state, “The security of our scheme is equivalent to the security of the underly- ing SAS protocol under the assumption that the user does not commit any errors.” This leaves open to what extent human errors may impact the security of the protocol and how these can be dealt with in the security analysis. We have shown that it is necessary to go beyond the presumption of humans acting perfectly. Indeed, their human study [9] clearly showed firstly that the humans did not act perfectly, and secondly that the level of error depended on the type of HPA used.

An interesting philosophical point is that even 1s and 0s for voltage levels in a circuit have already undertaken a transform to be human recognisable. So the SASs of Pasini and Vaudenay could be considered HPAs, and the subsequent lights by Prasad and Saxena are also, though different, HPAs from different HPASpaces.

Instead of the human being pre-loaded with a HPA and being sent a HPA ′ as the two HPA inputs to the Recognise function, HPA A will be on device A, and HPA B will be on device B. The formalisation for the human specific version of Recognise, including the
4.2 Proof of human-assisted device pairing protocol

A Bellare-Rogaway 1993 based model [1] was used to provide a security proof for Pasini and Vaudenay’s SAS protocol [8], upon which Prasad and Saxena based further human centred protocols [9]. However, in Prasad and Saxena’s work, no formal security analysis could be given to the BEEP-BEEP, BLINK-BLINK and BEEP-BLINK variations of the underlying SAS protocol. Rather, the claim was made that the derived protocols had equivalent security to the underlying SAS protocol [8] under the assumption that the human did not commit any errors [9].

Now, with our formalisation, the security framework exists to formally analyse such protocols.

4.2.1 Adversarial model

Recall the model for short authentication string-based pairing security, described by Pasini and Vaudenay [8] based on Bellare and Rogaway’s model [1]. An outline of Pasini and Vaudenay’s model is described here for completeness:

**Launch** (**n, role, x**) launches a new protocol instance on node **n** playing **role** (e.g. either Alice or Bob) with input **x**. It returns a new instance tag **πn**.

**Send** (**y, x**) sends an incoming message **y** to the instance **π**. It returns an outgoing message **z**, or the final output of the protocol if it completed.

**Corrupt** (**n**) injects a malicious code in node **n** so that its behaviour is no longer guaranteed.

These queries are standard in cryptographic models. For example, the **Send** query allows the adversary to run the protocol normally and to inject messages of his choice, reflecting the assumption that the adversary controls communications between protocol participants. The **Launch** oracle creates a unique tag **πn**, which allows node **n** to have multiple protocol instances running. **Corrupt** allows the adversary to effectively take over a node, meaning that any code the adversary wishes could be injected at the corrupted node such that the node would do what the adversary wants.

In the model, the participants **IDn** are located at nodes in the network. In Pasini and Vaudenay’s proof for their protocol [8] the winning condition for the adversary in such a message cross authentication protocol is “if some instance ended on an uncorrupted node with a pair (**m, ID**), but no instance on the node of identity **ID** with input **m** was launched.” For a complete description of the model, see [8].

**Theorem 1** (Success probability of Beep-Blink protocol). Let ζ be A’s success probability of the SAS protocol of Pasini and Vaudenay [8], then A’s success probability of the Beep-Blink protocol of Prasad and Saxena [9] is bounded by ζ + Succ_{A,Human}.

**Proof.** We employ the Shoup’s game hopping proof technique [12] augmented by Dent [4]. We employ a sequence of two games, the first game being the security game for the protocol shown in Figure 5 which is the human protocol of Prasad and Saxena represented with our formalism. We transform this to the security game for the original protocol of Pasini and Vaudenay shown in Figure 3 [8], bounding the adversary’s advantage between the two. As such our proof augments the proof of Pasini and Vaudenay to cater for the human considerations of the Prasad and Saxena protocol. We denote Win_i as the probability of the adversary winning game i.

**Game G0** describes the real protocol, as run by Prasad and Saxena [9], using our formalism (see Figure 5 and Figure 3). The game is played between a probabilistic polynomial time (PPT) bound adversary A and a simulator. The simulator simulates protocol participants as specified in the natural protocol specification, and answers all of A’s queries.

**Game G1** describes a game which is the same as Pasini and Vaudenay’s SAS protocol [8].
ference between Game $G_1$ and Game $G_0$ is that in Game $G_1$, the original SAS protocol, the authentication comparison is based on the human formalism, whereas in Game $G_0$ the authentication comparison is based on equality, which is the number of participants, $N$ is the number of runs of the protocol, and $p$ is the attack probability, with the example given for ATM-like PIN numbers of $p = 3 \cdot 10^{-4}$. Our formalism gives more meaningful values for $p$, taking into account human imperfection, and allows for the comparison of representational transform techniques (such as beeps and blinks). This means a more accurate security parameter of $p$ could be calculated.

In this way, a general framework may be created for all such unauthenticated key exchange protocols followed by HPA recognition.

5 Conclusion and Future Work

This work presents a method of accumulating data which will allow for the comparison of schemes in which the human will need to recognise some data. When represented formally using our technique, schemes can be compared using: the size of $\text{HPASpace}$ (maximise) and $\text{HPASpace}^H$ (maximise) and the ratio between the two (bring to equality); the size of $W_{H,\text{HPA}}$ (false positives, minimise); and the frequency of use per run of the protocol, and $p$ is the attack probability, with the example given for ATM-like PIN numbers of $p = 3 \cdot 10^{-4}$. Our formalism gives more meaningful values for $p$, taking into account human imperfection, and allows for the comparison of representational transform techniques (such as beeps and blinks). This means a more accurate security parameter of $p$ could be calculated.

We have provided an upper bound on the adversary’s probability of success, both for the case of a human generated HPA and a device generated HPA. We have shown how our formalism may be included easily into existing proofs, providing a more complete model in the case of mutual authentication over TLS, and creating a formal proof of human-assisted device pairing protocols to be created for the first time. Many similar examples of protocols involving humans where our formalism will be directly useful exist. Such an example would be standard Verified-by-Visa protocol implementations, where, due to the large numbers of people and the large numbers of protocol runs, useful values for each of the variables in our formalism will be available. At the softer end of the scale, our formalism could be applied to human protocols which exist completely in the human realm, for example where a human may have to authenticate themselves to another human which is typically based on some sort of recognition.

This paper presents a significant building block in security proofs which is useful in the sense that the formalism can be used in security proofs which allow the comparison of practical and real-world implemented human authentication schemes. However, further work can be pursued in at least two main areas. Firstly, for the purposes of creating a bound on the adversary’s success, in our model we have prevented $A$ from selecting a HPA that is outside of $\text{HPASpace}$, allowing $A$ to select a HPA that is outside of $\text{HPASpace}$ would increase the size of $W_{H,\text{HPA}}$ in Figure 1. Secondly, exploration and formalisation of the concept of context, thus making the analysis probabilistic not deterministic, will be a significant expansion of our work.
